ABSTRACT

The adsorption-desorption mechanisms at the interface between organic and inorganic soil colloids influence the movement of pesticides and hence their bioavailability and biotransformation processes. Direct analyses of soils have been reported in the literature with the use of solid-state nuclear magnetic resonance (NMR) spectroscopy on dry samples. We recently demonstrated the potential of the ¹H high resolution magic angle spinning (MAS) NMR technique to study such mechanisms *in situ* on highly hydrated samples. By using a well-characterized soil model, it was possible to distinguish the mobile and immobile pesticide unambiguously. In the present communication, a short review of MAS NMR techniques that allow covalent and non-covalent bond analysis is provided. The results obtained in our group on the adsorption of some pollutants such as phosphonomethylglycine (glyphosate), MCPA and 2-benzothiazole sulphonate are also presented. Specifically, we focus on the potential of MAS NMR spectroscopy for probing the behaviour (mobility) of these organic pollutants loaded onto the surface of different clays. The influence of clay hydration on NMR spectra has also been evaluated.

Introduction

The fate of organic pollutants in the environment is strongly dependent on the interactions they can make with organic (humic and fulvic acids) and inorganic (clays, metal (hydr)oxides) soil constituents (Cornejo & Jamet, 2000). The strength of these interactions controls not only the potential of the pollutant to reach groundwater but also its bioavailability towards microorganisms or plants. Numerous studies have documented the key role of organic matter in the sorption of non-polar compounds (Spark & Swift, 2002, and references cited therein). However, clay particles, due to their small size (< 2 µm), large surface area (100–800 m² g⁻¹), ion exchange properties and open layered structure, can also make a considerable contribution to the pollutant sorption process (surface and inter-crystallite adsorption, intercalation or irreversible grafting), especially when the pollutant is polar (even weakly so) (Gilchrist *et al.*, 1993; Laird & Sawhney, 2002). Indeed, adsorption properties of soils are mainly due to phyllosilicates, hydrated oxides and hydroxides either in their natural state or associated with humic substances (Matthes & Kahr, 2000; Laird, 2004; Vereecken, 2005; Gimsing *et al.*, 2007).

When covalent bonds are created, the pollutant forms bound residues with soil that are no longer extractable or bioavailable. It can participate in the humification process or induce some eco-toxicological problems. The pollutant can also interact with weak bonds; in that case it is likely to be more bioavailable for microbes or plants or be transported to ground water. Studying these interactions at a molecular level or, more macroscopically, studying the mobility of the pollutant is not an easy task.

Nuclear magnetic resonance (NMR) spectroscopy is a useful method to assess molecular mechanisms. Most of the studies published are focused on organic matter (OM) composition in terms of its geographical origin and/or the treatment to which it has been submitted by using the classical ¹³C cross-polarization magic angle spinning (MAS) solid state NMR sequence. Comparatively, the behaviour of organic pollutants in soils or soil fractions has been less studied. Nevertheless, various NMR approaches have been developed to study covalent and non-covalent interactions between pollutants and soil (Nanny *et al.*, 1998; Combourieu *et al.*, 2005). It should be noted that, due to the relatively low sensitivity of NMR techniques, reported studies were carried out exclusively under laboratory and not under field conditions, usually with ¹³C or ¹⁵N-labelled compounds to allow specific detection of residues resulting from covalent bonding (the concentration of the organic pollutant compared with the amount of soil organic matter is very small). This limitation explains why only a few types of compound have been studied to date. 1D and 2D ¹⁵N-¹³C DCP-MAS (double cross polarization magic angle spinning) NMR

techniques, which allow specific identification of ^{13}C -NMR signals of ^{13}C atoms directly bound to ^{15}N atoms, have been used successfully to give evidence of covalent bonds between ^{15}N -TNT (trinitrotoluene) and carboxylic and methyl groups of humic acids (Knicker, 2003). This technique is extremely powerful and novel but remains limited by its poor sensitivity.

Non-covalent interactions imply a rather high degree of mobility of the molecules, which are usually in a hydrated environment. Consequently, the various strategies to study these interactions are aimed at assessing this mobility.

First, an indirect approach consists of establishing correlations between organic carbon normalized sorption coefficients (*K*_{oc} values) of organic pollutants with soil matrices and structural elements of soil organic matter (OM). These correlations should, in principle, allow extrapolation to possible interactions between a pollutant and soil OM. NMR only plays a role in determining the structural groups of OM. The techniques used are mainly CPMAS ^{13}C NMR at natural abundance, but also liquid state ^{13}C NMR for model compounds (Golding *et al.*, 2005; Oren & Chefetz, 2005; Ahmad *et al.*, 2006; Smernik *et al.*, 2006; Bonin & Simpson, 2007). However, many of these correlations are unsatisfactory when the pollutant bears polar functions and depend on the percentage or the nature of the OM present.

A second approach takes advantage of NMR properties connected to the orientation or movement of the molecules. For instance, because of the specific properties of the ^2H nucleus, ^2H MAS-NMR spectra can be used as 'fingerprints' of orientation and movement of ^2H -labelled pollutants within a solid matrix. This approach is based on the comparison of experimental and simulated spectra (Emery *et al.*, 2001) and this technique requires labelled compounds.

The T_1 relaxation time is basically an NMR parameter that reflects the intrinsic mobility of each atom, as T_1 is inversely proportional to the correlation time, τ_c . In other words, the greater T_1 , the more mobile the atom. Decrease in T_1 reflects a stronger interaction between the pollutant and the matrix (Nanny & Maza, 2001).

A last class of NMR experiment carried out on hydrated solid matrices (peat, soil, clay), which can be considered as more relevant to real environmental conditions, allows study of molecular species at the liquid/solid interface. Basically, the NMR signals detected reflect the degree of mobility of these species: highly mobile molecules give narrow signals, similar to liquid state NMR spectra; in contrast, when the strength of the interaction increases, the signals become progressively broader. Reported studies in this field have been performed at natural abundance on certain pollutants, without labelling them, using ^{19}F or ^{31}P (efficient but restricted to those containing at least one such atom) (Kohl *et al.*, 2000; Seger & Maciel, 2006) or ^1H NMR. The ^1H is present in almost all organic pollutants and has the greatest sensitivity. Therefore, ^1H NMR is the most promising for general application. In the past, its use was very restricted because of the narrow range of chemical shifts, the interference with other protons of the matrix and the strong dipolar coupling constants, which gave very broad lines when ^1H solid-state NMR was used. The very recent development of the ^1H HR-MAS (high resolution magic angle spinning) technique combined with specific HR-MAS probes that allow the use of gradients and shimming coils, opens a new field in environmental studies. Basically, this technique allows the characterization by NMR of inhomogeneous compounds with liquid-like dynamics (Piotto *et al.*, 2001; Simpson *et al.*, 2006). It has also been applied to study the interactions of pesticides with soil (Simpson *et al.*, 2001) or clay (Combourieu *et al.*, 2001). Interactions between pesticides and the surrounding soil matrix, swollen in water, could be observed despite the massive presence of water in the samples.

The purpose of the present communication is to evaluate the potential of MAS NMR spectroscopy for probing the behaviour (mobility) of organic pollutants loaded onto the surface of different clays: cationic (montmorillonite) and anionic (hydrotalcite-like materials, named layered double hydroxides or LDHs). The influence of clay hydration on NMR spectra has also been evaluated. Our NMR results are compared with those obtained with Fourier transform infrared (FTIR) spectroscopy and X-ray diffractometry. Three ionic organic pollutants have been chosen: two well-known and widely used herbicides (4-chloro-2-methylphenoxyacetic acid (MCPA) and N-phosphonomethylglycine (glyphosate)) and an industrial pollutant of the widely used benzothiazole family: 2-benzothiazolesulphonate (BTSO_3) (Figure 1). Benzothiazoles (BTs) have many applications: fungicides in lumber and leather production, antifungal agents, slimicides in the paper and pulp industry, chemotherapeutic agents, and vulcanisation catalysts (see De Wever *et al.*, 2001). BTSO_3 is a by-product of an industrial process but is also released from manufactured compounds that contain BTs. Therefore, BTSO_3 has been detected not only in industrial

wastewaters but also in various environmental compartments (Reemtsma *et al.*, 2006). In the case of BTO₃, the potential of MAS NMR to monitor its biotransformation *in situ* by the bacterial strain *Rhodococcus erythropolis* in the presence of anionic clays is presented.

Figure 1 Chemical structures of 4-chloro-2-methylphenoxyacetic acid (MCPA), N-phosphonomethylglycine (glyphosate, PMG) and 2-benzothiazolesulphonate (BTO₃).

Materials and methods

Chemicals

BTO₃ was donated by Bayer (Antwerp, Belgium); N-phosphonomethylglycine (95%) was purchased from Aldrich (Saint-Quentin Fallavier, France); MCPA (sodium salt) was purchased from Fluka (L'Isle d'Abeau, France); and tetradeuterated sodium trimethylsilylpropionate (TSPd₄), hexadeuterated sodium 3-trimethylsilyl-1-propanesulphonate (DSS) and D₂O (99%) were purchased from Eurisotop (Saint Aubin, France).

Preparation and characterization of clay samples

Montmorillonite KSF was purchased from Aldrich (batch no. 28,153-0), and the LDHs were prepared in the laboratory as described by Inacio *et al.* (2001). The mineralogical composition of clays was determined by X-ray diffractometry (CuK α radiation; Philips X'Pert automated X-ray diffractometer). The samples were step-scanned in increments of 0.08° 2 θ and 4s per step counting time. Powder XRD patterns were recorded in order to determine whether pollutants were intercalated in the layers or adsorbed on the surface. The choice of an acid activated montmorillonite (KSF) was guided by some recent results concerning glyphosate adsorption: decreasing pH and increasing ionic strength lead to an increase of surface coverage and thus glyphosate adsorption (Damonte *et al.*, 2006). These relatively large adsorption capacities may be suitable to evaluate the potential of MAS NMR to study the behaviour of glyphosate as sensitivity of NMR is rather low.

Adsorption isotherms

The adsorption isotherms were determined according to the OECD Guideline 106 (OECD, 2000) with a batch equilibrium method at 25°C. Each experiment was repeated twice. The samples were dispersed in decarbonated deionized water (10 or 50 ml) in order to obtain a homogeneous dispersion and stirred for 24 hours before the pollutant was added. In the case of LDHs, the pH was adjusted to 7.5 by HCl (0.1 mol litre⁻¹) or NaOH (0.1 mol litre⁻¹). Montmorillonite KSF buffered the medium to pH 4 (no change during sorption process): thus no pH adjustment was necessary. After a contact time of 24 hours, the suspensions were centrifuged (10 minutes, 12 500 g). In the case of MCPA, some adsorption isotherms were carried out in fully (99%) deuterated water to minimize contributions of clay protons during ¹H MAS NMR experiments. Solid-liquid ratios were: 100 mg in 10 ml (1/100) and 50 mg in 10 ml (1/200) for glyphosate; 50 mg in 50 ml (1/1000) for MCPA; 50 mg in 50 ml (1/1000) and 500 mg in 10 ml (1/20) for BTO₃. In the case of BTO₃, the adsorption isotherms were recorded at pH 8.0 in a concentration range between 0.10 and 2.0 mmol litre⁻¹ for the two solid-liquid ratios. It should be noted that at this pH, BTO₃ may be principally present in its sulphonate form.

The amount of pollutant adsorbed by clays (*C_s*) was determined from the difference between the initial (*C_i*) and final (or equilibrium) concentrations (*C_e*) of the pollutant per gram of clay adsorbent: $C_s = (C_i - C_e) \times V/m$ (Equation 1), where *V* (litre) is the volume of the mixture and *m* (gram) is the mass of clay. The adsorption isotherms were obtained by plotting the amount of pollutant adsorbed (*C_s*) versus the adsorbate concentration in the equilibrium solution (*C_e*).

Measurements of pollutant concentrations

MCPA concentrations were determined by UV spectrophotometry by measuring the absorbance at 279 nm with a Perkin-Elmer Lambda 2S UV-Visible spectrometer (Courtaboeuf, France). Concentrations of BTSO₃ were measured by reversed-phase HPLC with a Perkin Elmer Series 200 chromatograph (Column SPHERI-5 RP-18; 5 µm, 250 × 4.6 mm) equipped with a DAD UV detector set at 298 nm. The mobile phase was acetonitrile/water (20/80 V/V); flow rate: 0.7 ml minute⁻¹. Glyphosate was detected after derivatization (Miles & Moye, 1988) by reversed-phase HPLC (Column Nucleodur C18, 5 µm, 150 × 4.6 mm) on an Agilent 1100 chromatograph (Massy, France) equipped with a fluorescent detector (270 nm for excitation and 317 nm for emission). The mobile phase was a mixture of phosphate buffer (50 mmol litre⁻¹ KH₂PO₄; pH adjusted to 6.0 with 2 mol litre⁻¹ KOH) and acetonitrile, 70/30 V/V; flow rate: 1 ml minute⁻¹.

FTIR measurements. FTIR spectra of the adsorbed pollutant-clay samples were recorded with a Perkin Elmer 16 PC FT-IR spectrophotometer on pellets by pressing, under vacuum, uniformly prepared mixtures of 2 mg of the solid investigated and 198 mg of spectrometry grade KBr. Pellets were measured immediately after pressing.

¹H liquid state NMR measurements. ¹H liquid state NMR was performed at 25°C at 500 MHz on an Avance 500 Bruker spectrometer (Bruker Biospin, Wissembourg, France) equipped with a triple-resonance (¹H, ¹³C, ¹⁵N) inverse probe with 5-mm diameter tubes containing 600 µl of sample, with water being suppressed by a classical two phase-shifted pulse saturation sequence. Approximately 256 scans were collected (90° pulse, 7.3 µs; saturation pulse, 3 s; relaxation delay, 3 s; acquisition time, 4.679 s; 65 536 data points). A 1-Hz exponential line-broadening filter was applied before Fourier transformation, and a baseline correction was performed on spectra before integration using Bruker software. Under these conditions, the limit of detection and quantification were within the range of 1–10 µmol litre⁻¹, respectively.

MAS NMR measurements. NMR spectra were performed on a Bruker Avance DSX-300 spectrometer or a Bruker Avance 500 spectrometer, both equipped with a double-bearing magic angle spinning (MAS) probehead. The samples were packed in 4-mm zirconia rotors fitted with Kel-F caps. For hydrated sample analysis (HR MAS), the volume was restricted to approximately 12 µl in the centre of the rotor by means of a Teflon insert.

The high-resolution ¹³C solid state spectra were performed at 75.46 MHz at the magic angle with a spinning rate of 10 kHz at ambient temperature. A ramped cross-polarization (RACP) sequence was used to enhance ¹³C magnetization. Hartmann-Hahn cross-polarization from protons to carbon was carried out at a proton nutation frequency of 70 kHz over a contact time of 1.5 ms, chosen according to variable contact time experiments. A TPPM decoupling with ¹H nutation frequency of 70 kHz, pulse length of 6.0 µs and phase shift of 15° was used. A recycle delay of 4 s was used. Free induction decays (FID) were digitized into 6K data points and Fourier-transformed after applying 5 Hz exponential line-broadening. The number of transients was fitted to reach optimal signal to noise ratios (2000–4096). The ¹³C chemical shifts were referenced to an external reference taken from the carbonyl group of glycine (176.03 p.p.m.).

¹H MAS and ¹H MAS Hahn echo experiments. These were carried out at 300.13 MHz. The high resolution component of a ¹H MAS spectrum can be well isolated from the broadline one by the Hahn echo sequence with a long echo time. Compared with the CRAMPS experiment (Duer, 2002), which measures the proton system as a whole, the high resolution echo-MAS method measures only a fraction of the solid, which is usually small at room temperature and quite different from the majority of the solid in both molecular motion and chemical environment. However, when several resonances with different chemical shifts exist, a long delay time will cause severe first-order phase distortion. The phase distortion usually becomes increasingly severe with increase in the delay time and the magnetic field. The Hahn echo pulse sequence (π/2-τ/2-π-τ/2-AQ) is found to be very useful for obtaining a pure absorption mode high resolution spectrum at both high field and longer delay times. In addition, a greater sensitivity is obtained by the echo sequence because the main field inhomogeneity is refocused. We have chosen to use a rotor synchronized version of this classical Hahn echo experiment in order to improve the efficiency of the refocalization. When τ is larger than 1 ms, a perfectly phased high resolution spectrum is obtained. As

for all spin echo experiments, the high resolution spectrum obtained by the echo-MAS experiment at an arbitrary τ value is generally not quantitative. Thus the choice of the echo value is a crucial issue. The spinning rate was 12 kHz for these experiments. A $\pi/2$ pulse of 3.9 μ s was used. A variety of echo times was evaluated (100 μ s–1.6 ms). A 3 Hz exponential line-broadening was applied before Fourier transformation. The same phase and baseline corrections were applied to all spectra. The chemical shifts were referenced to TSPd₄ taken as an external reference.

¹H HR-MAS experiments. To assess the mobility of adsorbed pollutants on clays, samples (15 mg) were swollen with 30 μ l of deionised water. The sample volume was restricted to approximately 12 μ l in the centre of the rotor by means of a Teflon insert. The spectra were recorded with a rotor-synchronized single pulse experiment ($t_{90^\circ} = 6.2 \mu$ s) with pre-saturation during the relaxation delay (3 s) for water resonance suppression. Its robustness was greater than that of the classical Watergate experiment in such heterogeneous samples. The samples were spun (ν_r) at 3 kHz. Chemical shifts are reported in p.p.m. relative to TSPd₄ as external standard. TSPd₄ was also used for quantification. The number of transients was typically 128 or 256 to achieve a good signal-to-noise ratio.

¹H T_1 measurements of BTSO₃ were carried out using the inversion-recovery sequence that included two water saturation periods during recycle and recovery delays. The measurements were repeated twice both on a pure BTSO₃ solution and on LDH-BTSO₃ complexes.

BTSO₃ biodegradation in the presence of clays. *Rhodococcus erythropolis* was grown and prepared as previously described (Besse *et al.*, 2001). Different quantities of LDHs (Mg₃AlCO₃: 10 mg, 250 mg, 500 mg, 1 g) were added to 8 ml of a 2 mmol litre⁻¹ BTSO₃ solution in deionised water containing or not an internal standard (DSS at 0.5 mmol litre⁻¹). The suspension was incubated in 50 ml Erlenmeyer flasks at 27°C, with shaking at 200 r.p.m. After 24 hours, a cell suspension (0.2 g wet weight biomass prepared as previously described (Haroune, 2003)) in 2 ml Volvic® (Danone, Volvic, France) water was added. This mineral water was chosen for its low and constant ion content (especially carbonates that can drastically affect adsorption properties). Incubation conditions were the same as those described previously (27°C, with shaking at 200 r.p.m). Samples (500 μ l) were taken regularly to be analysed by HPLC and ¹H liquid state NMR after centrifugation (12 500 g, 10 minutes). Concomitantly, 12 μ l samples of the suspension (without centrifugation) were taken and introduced into a 4-mm zirconia rotor to be directly analysed by ¹H HR-MAS NMR (without any treatment). Controls without cells were prepared under the same conditions. Controls were also prepared to evaluate the impact of DSS on BTSO₃ metabolism.

Results and discussion

Adsorption and properties of glyphosate adsorbed on montmorillonite KSF

Two solid-liquid ratios were used (1/100 and 1/200) and gave similar results. Isotherms of glyphosate (PMG) adsorption on this montmorillonite are all non-linear, have two steps and indicate that ligand exchange is the main adsorption mechanism (Figure 2).

Figure 2 Isotherm of glyphosate adsorption on montmorillonite KSF for a 1/200 solid-liquid ratio.

X-ray diffractograms were made for material representing each point of the isotherm and indicated an increase in the basal spacing from 11.8 to 13.2 Å. This increase in the interlamellar distance appears

insufficient for guest PMG between the sheets. It is clear that glyphosate may interact with a positively charged surface through its ammonium moiety. However, to be intercalated into the sheets, PMG must be oriented parallel to the layers and the minimum distance for this was calculated to be 4 Å. No other significant structural changes were observed after adsorption.

The FTIR spectra of pure and exchanged montmorillonites were similar (data not shown). The content of physisorbed water was greater after adsorption of PMG. Vibrational bands of PMG were systematically masked by those of the clays. Consequently, FTIR spectroscopy is not an appropriate method in this case. Thus, we recorded ^1H MAS Hahn echo spectra with a 1 ms echo time (data not shown). However, mobile water resonance dominated the spectra, avoiding unambiguous data analysis. The same samples were subsequently hydrated (200% w/w) and analysed by ^1H 1D HR-MAS NMR. The primary aim was to mimic environmental conditions more reasonably, in which water content usually plays an important role in the fate of pollutants. Moreover, it thus may be possible to increase the mobility of the adsorbed PMG. By this means, we expected sharper signals. The ^1H HR-MAS spectra of hydrated samples are presented in Figure 3(b–d). Resonances in the range 2.1–2.3 p.p.m. belong to 'impurities' of montmorillonite 'salted out' during adsorption of PMG. These resonances were not present in the PMG solution and they were not observed when montmorillonite was analysed just after swelling (Figure 3a). The major features of these spectra were as follows. (i) The high resolution of the spectra containing PMG, with its resonances clearly observed at 3.24 and 3.82 p.p.m., the $^2J_{\text{H}-\text{P}}$ coupling constant (11.5 Hz) being observed on some spectra. (ii) PMG signal intensities increased with the amount of PMG loaded onto the surface. It indicates that NMR preserves its quantitative properties despite the heterogeneous state of the samples. (iii) Signals were rather sharp, suggesting a relatively weak interaction between PMG and the negatively charged surface. This hypothesis is reasonable bearing in mind that PMG must interact with the montmorillonite surface by its ammonium moiety, contrary to previously published studies on goethite in which PMG entered the coordination sphere of iron via one of its phosphonate oxygens (Sheals *et al.*, 2002). Further experiments are in progress in our group to confirm the nature of the interaction of PMG with the surface of this montmorillonite.

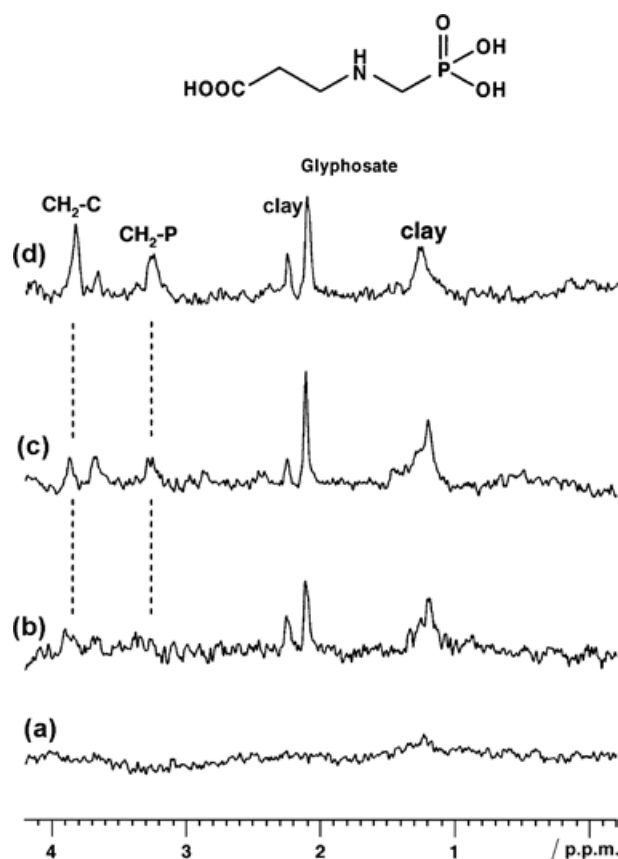

Figure 3 ^1H HR-MAS spectra of hydrated (200% w/w) PMG-montmorillonite phases obtained after PMG adsorption for a 1/200 solid-liquid ratio (spinning rate: 3 kHz). From bottom to top: Cs = 0, 0.12, 0.16 and 0.29 mmol g $^{-1}$. Note that (a) corresponds to the spectrum of the hydrated montmorillonite.

Thus, to increase our knowledge of the mechanisms involved at the solid-liquid interface, we decided to simplify the solid model.

MCPA adsorption

To evaluate the potential of MAS NMR to study interactions between MCPA and fully characterized hydrotalcite-like materials (LDHs), adsorption isotherms were determined in water or deuterated water. The shape of the isotherms makes it difficult to classify them. The isotherms resemble S-type isotherms but tend to L-type for C_e 1.5 mmol litre⁻¹. The changes from S to L types within the same isotherm are likely to be due to changes from external to interlayer adsorption. Indeed, at a C_e value of 1.3 mmol litre⁻¹, intercalation proceeds via an increase of the basal spacing from 7.94 Å for [Mg₃AlCl] to 22.1 Å for [Mg₃AlMCPA] as shown by powder X-ray diffraction. We have previously shown that ¹³C CP MAS spectra recorded on dry samples clearly showed the presence of adsorbed and intercalated MCPA in the clay samples (Combourieu *et al.*, 2001). The various carbons of the MCPA molecule did not shift compared with free MCPA. A slight difference of relative CO₃²⁻ and C₁ signal intensities for the two populations (adsorbed and intercalated) was due to the poorer efficiency of the polarization transfer between ¹H and ¹³C nuclei located at the surface. Improved resolution of the intercalated MCPA spectrum can be explained by greater structural order of this solid phase. Solid state ¹H MAS experiments made on both adsorbed and intercalated clays showed very broad signals and did not allow differentiation of both populations of MCPA. This is easily explained by the presence of a large number of protons in LDHs, mainly from hydroxides, structural and physisorbed water. To solve this problem, adsorption isotherms were obtained in deuterated water. The ¹H MAS spectrum corresponding to C_e (1 mmol litre⁻¹) is shown in Figure 4(d) and was compared with that of intercalated MCPA (Figure 4c). Greater resolution of the spectra was possible but adsorbed and intercalated samples could not be differentiated by this means.

Figure 4 ¹H MAS spectra of hydrated samples obtained during the adsorption (a), the intercalation (b) of MCPA on the Mg₃AlCl phase. The exchanges were carried out in D₂O. ¹H MAS spectra of dry samples: (c) intercalated, (d) adsorbed and (e) precursor material.

The next step was to hydrate the samples strongly and to record the ^1H HR-MAS NMR spectrum at a slow spinning rate (< 6 kHz). As mentioned above, in HR-MAS NMR, the signals detected basically reflect the degree of mobility of the species loaded onto the surface of a solid matrix: very mobile molecules give narrow signals, close to those of liquid-state NMR spectra. In contrast, when the strength of the interaction increases, the signals are broader. In this way, despite the massive presence of water in the samples, we were able to differentiate adsorbed versus intercalated MCPA (Combourieu *et al.*, 2001). The adsorbed species gave sharp signals, close to those of liquid state ^1H NMR ($^3J_{\text{H}-\text{H}}$ coupling constants are visible), indicating great mobility at the solid-aqueous interface. In contrast, the intercalated species gave very wide, unresolved resonances due to their strong interactions with the clay. Thus, it appears that HR-MAS NMR performed on greatly hydrated samples was suitable to discriminate different species (mobile and immobile) of a pesticide loaded onto the surface of anionic clays. In order to generalize this simple approach to other pollutants and materials, we have investigated the behaviour of another organic pollutant on LDHs.

Behaviour of 2-benzothiazole sulphonate loaded on anionic clays

BTSO₃ adsorption. The adsorption on the chloride phase was stronger for the 1/1000 solid-liquid ratio (Figure 5). It may be due to a more favourable dispersion effect. The BTSO₃ adsorption on the carbonate phase (1/1000 ratio) was less strong than for the chloride one (Figure 5a). This result, enhanced for $C_e < 1$ mmol litre⁻¹, is explained by the strong affinity of carbonate ions for the positively charged LDH surface. Indeed, for $C_e < 1$ mmol litre⁻¹ competition by carbonate affected BTSO₃ adsorption at the surface. With a 1/20 solid-liquid ratio, no significant BTSO₃ adsorption was observed for this carbonate-containing phase (data not shown) while little adsorption occurs for the chloride phase (Figure 5b), with C_s values roughly 100 times less than for the 1/1000 solid-liquid ratio.

Figure 5 Isotherms of BTSO₃ adsorption (a) on Mg₃AlCO₃ (x) and on Mg₃AlCl for a 1/1000 solid-liquid ratio (•) and (b) on Mg₃AlCl for 1/20 solid-liquid ratio (▲).

For the various phases, the different solid-liquid ratios and for each point of the isotherms, dry samples were analysed by X-ray diffraction, FTIR and MAS NMR spectroscopy. However, to simplify the following discussion, only results concerning the chloride phase are presented because conclusions are similar for all phases.

For a 1/20 solid-liquid ratio, the XRD patterns did not reveal any modification of mineral structures compared with the precursor phase, whatever the initial concentration of BTSO₃. However, for a 1/1000 solid-liquid ratio, new diffraction peaks appeared at $2c/3$ ($c = 2$ mmol litre⁻¹) (Figure 6). Intercalation of BTSO₃ anions in the lamellar host structure was clearly demonstrated by the increase in the basal spacing, from 7.68 Å for the chloride precursor to 18.2 Å for the organic intercalate (Figure 6). This distance suggests that the sulphonate moiety interacts directly with the positively charged mineral surface, the benzene ring being perpendicular to the layers. No intermediate distance was observed on spectra below

concentrations of $2c/3$, indicating that the adsorption – intercalation process was an anion exchange mechanism.

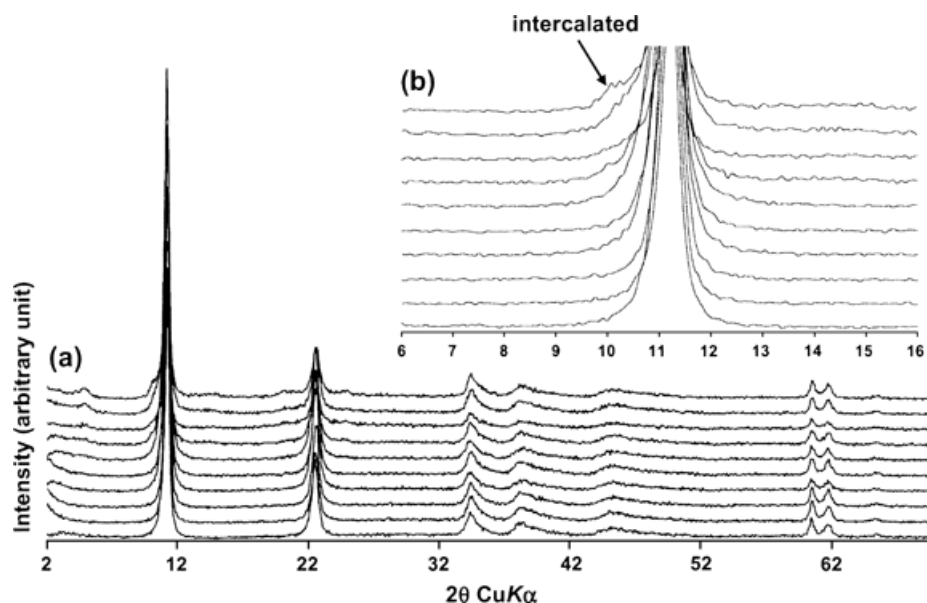

Figure 6 (a) X-ray diffraction patterns recorded after adsorption of BTSO₃ on Mg₃AlCl material for a 1/1000 solid-liquid ratio. From top to bottom: c (2 mmol litre⁻¹), 3c/4, 2c/3, c/2, c/3, c/4, c/5, c/10, c/20, blank. (b) Expanded region.

FTIR spectra of the Mg₃-Al-Cl precursor and the BTSO₃ exchanged samples in a solid-liquid ratio of 1/20 were identical. No vibrational band of BTSO₃ was visible, although the adsorption isotherm clearly indicated an adsorption process (Figure 7). For a 1/1000 solid-liquid ratio, vibration modes of BTSO₃ were visible from concentrations of c to c/4 but not below. The S=O band was shifted from 1250 to 1222 cm⁻¹ after exchange, suggesting greater covalent character. The C=N band (1260 cm⁻¹) was unaffected by adsorption and/or intercalation during exchange. This result confirmed that BTSO₃ interacts with the surface by its sulphonate moiety. However, the spectra did not show any change between adsorbed and intercalated samples. This result indicates a similar interaction between the pollutant and clays during adsorption and intercalation, with BTSO₃ being perpendicular to the sheets.

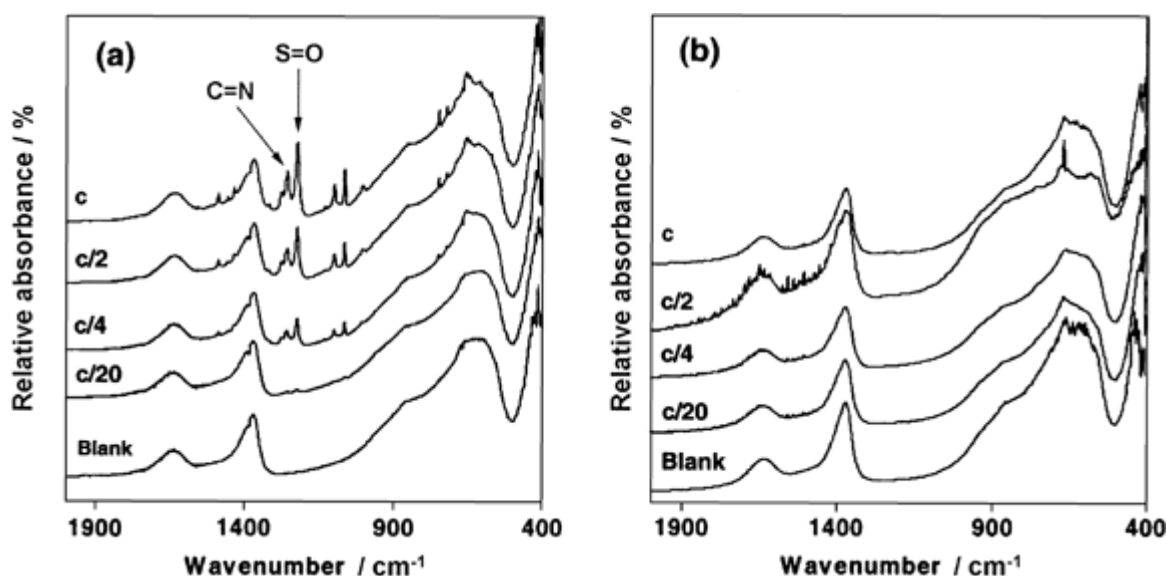

Figure 7 FTIR spectra of Mg₃AlCl after adsorption of BTSO₃; (a) 1/1000 and (b) 1/20 solid-liquid ratios.

MAS NMR

To compare FTIR spectra recorded on dry samples with NMR data, CPMAS ¹³C experiments were performed on dry samples (Figure 8). Resonances between 119 and 130 p.p.m. correspond to carbons C4, C5, C6 and C7 (see Figure 8 for carbon numbering). The apparent loss of a resonance in Figure 8(b) is due to a small variation in chemical shift consequent on a π - π stacking effect between two BTSO₃

aromatic rings. Moreover, the poorer resolution – probably due to a greater disorder at the surface after adsorption of BTSO_3^- – does not allow observation of all resonances. Small variations in carbons C3a and C7a ^{13}C chemical shifts and in the shape of signals were observed between pure and adsorbed and/or intercalated BTSO_3 samples. The C2 resonance was also shifted by 3 p.p.m., which suggests the involvement of the sulphonate group in the interaction with clays. However, these slight changes do not allow us to determine a particular geometry for the pollutant. The same effect as that described for MCPA was observed for intensities. Quantities of BTSO_3 loaded in intercalated samples were about 10 times greater than those present in adsorbed samples. Consequently, the source of protons was bigger and the polarization transfer more efficient for intercalated samples. Therefore, CPMAS ^{13}C NMR did not provide new information on the kind of interactions involved. Nevertheless, it should be noted that both 1/20 and 1/1000 solid-liquid ratios gave identical results for intercalated versus adsorbed samples.

Figure 8 CPMAS ^{13}C NMR spectra of (a) pure, (b) adsorbed and (c) intercalated (co-precipitated) BTSO_3 on the Mg_3AlCl phase. Spinning rate: 12 kHz.

To obtain more information from NMR data, ^1H Hahn echo experiments were carried out on dry samples (Figure 9).

Figure 9 ^1H MAS Hahn echo spectra of the BTSO_3 - Mg_3AlCl phase obtained (a) for 1/20 and (b) 1/1000 solid-liquid ratios. The percentages correspond to signal area normalized to the greatest concentration used in the adsorption isotherms. Blank: spectra of precursor, without BTSO_3 .

Hahn echo experiments were carried out for the two solid-liquid ratios and each point of the isotherms was analysed by this sequence. Varying echo times provided useful results. At an echo time of 410 μs , the residual of the broadline component was still visible (data not shown). For an echo time of 825 μs , the spectrum was dominated by the high-resolution component and the intensity of the broadline component

was greatly reduced. Quantification was then possible. Above 900 μs , most of the high-resolution component was lost. For the 1/20 solid-liquid ratio, ^1H Hahn echo spectra showed that signal intensities increased with the quantity of BTSO_3 adsorbed onto the surface. Conversely, the ^1H NMR signals decreased for the 1/1000 solid-liquid ratio while the amount of BTSO_3 loaded onto the material increased. These results were complementary to the FTIR and X-ray diffraction pattern data. They may be explained thoroughly because a complete mathematical development exists for the Hahn echo experiment (Bilski *et al.*, 2002). It has been established for the two types of solid echo experiments ($\pi/2$ - $\tau/2$ - π - $\tau/2$ -AQ and $\pi/2$ - $\tau/2$ - $\pi/2$ - $\tau/2$ -AQ) that time position and amplitude of the solid-echo maximum depend on the correlation time, τ_c , of molecular motion, and on the width of the RF pulses. When the pollutant is constrained near the surface or intercalated into the lamellar host, a slow-motion region may be reached. Consequently, the amplitude of the echo signal is reduced and its maximum is shifted to the end of the second pulse. It thus appears that the signal intensity in a Hahn echo experiment can be used to appreciate the global 'molecular dynamic process' or more generally the 'macroscopic mobility' of an organic pollutant loaded onto the surface of a solid matrix. Thus, the use of such a NMR experiment may be appropriate only when there is little adsorption, which is the dominant situation in the environment.

^1H HR-MAS 1D experiments

Further experiments were carried out on greatly hydrated (200% w/w) samples in order to appreciate the various degrees of mobility of the pollutant. The BTSO_3 signals were well resolved. For the 1/1000 solid-liquid ratio, BTSO_3 concentrations found in heterogeneous media by HR-MAS and in solution by liquid-state NMR were similar. This indicates that under these conditions HR-MAS only reflects the fraction of the pollutant with a great mobility; that is, interacting weakly with the surface. Thus, the small fraction of BTSO_3 strongly adsorbed onto clays (as shown by adsorption isotherms) cannot be observed by HR-MAS, contrary to ^1H MAS NMR performed on dry samples with high-power amplifiers. This result is consistent with that found for MCPA. For the ratio 1/20, the same results were observed. The sole limitation is the relatively high detection threshold of HR-MAS (measured at 30 μM in our conditions) because adsorbed quantities are less in this case (Figure 5).

Then, we estimated the strength of the interaction in the case of weak adsorption via longitudinal relaxation times (T_1) of both BTSO_3 and the internal standard (TSPd₄).

Longitudinal relaxation time (T_1) measurements by ^1H HR-MAS

An inversion-recovery sequence including water saturation during recycle and recovery delays was used. In the presence of clays, a decrease of T_1 was observed for all signals (Table 1), thus indicating *a priori* less mobility of organic compounds. This may be due to weak interaction with the surface and is consistent with results previously described.

Table 1 ^1H Longitudinal relaxation of BTSO_3 signals and TSPd₄ measured directly by HR-MAS in the presence or the absence of clays

	TSPd ₄		BTSO ₃	
	0 p.p.m.	7.64 p.p.m.	7.70 p.p.m.	8.14 p.p.m.
Without clays	3.511	4.409	4.278	5.660
With clays	2.948	3.695	3.171	4.646

BTSO_3 metabolism in the presence of clays

We have recently established the full metabolic pathway of BTs, including BTSO_3 , by *Rhodococcus erythropolis* in homogenous suspension (without clays) on a laboratory scale (Haroune, 2003). In the presence of clays, the degradation rate of BTSO_3 decreased substantially due to the poorer bioavailability of the pollutant. The potential of ^1H HR-MAS NMR spectroscopy to study this biodegradation in the presence of clay was tested. Our aim was to check whether the fraction of the pollutant interacting with clays (as suggested by the T_1 data) was less bioavailable than that 'free' in the medium.

The kinetics of degradation obtained by ^1H HR-MAS (without centrifugation) were compared with those analysed by HPLC and liquid state ^1H NMR after centrifugation. In this case, DSS was chosen as the internal standard. Indeed, it is not transformed either chemically or biochemically in the presence of clays, contrary to TSPd₄. Moreover, it is not significantly adsorbed onto LDHs. Finally, DSS does not affect the bacterial metabolism of BTSO_3 .

The ^1H HR-MAS spectra of these complex and heterogeneous mixtures are presented in Figure 10. Note that despite the presence of cells and clay particles, spectra were of good quality, with BTSO_3 signals sharp and well resolved. This sharpness suggests a great mobility of the pollutant. The analyses of supernatants after centrifugation (12 500 g, 10 minutes) showed that with 10 mg of LDHs, no difference was observed compared with controls without clays (data not shown). From 250 mg to 1 g of LDHs, the degradation rate decreased slightly but not significantly. The pH, increasing from 8.3 to 8.9 with the amount of hydrotalcite (from 10 mg to 1 g), was not responsible for this slight decrease. Controls without clay particles but with various ions introduced in the medium (as HCl , MgCl_2 or MgCO_3 , NaCl or NaOH) revealed that they were responsible for this decrease (inhibition of some metabolic pathways). Nevertheless, no metabolites of BTSO_3 were observed in either case, BTSO_3 being partially mineralized.

Figure 10 *In situ* ^1H HR-MAS NMR spectra of samples taken at 5 minutes, 2, 4, 6 and 8 hours of incubation of $2 \text{ mmol litre}^{-1}$ BTSO_3 with resting cells of *Rhodococcus erythropolis* in the presence of 10 mg anionic clays ($\text{Mg}_3\text{Al}(\text{OH})_4(\text{CO}_3)_2$).

The analysis of the medium performed directly by ^1H HR-MAS without centrifugation showed a similar degradation curve even if only small differences were observed in the degradation compared with results obtained from HPLC or ^1H liquid-state NMR of supernatants (Figure 11). The most important change concerned the initial BTSO_3 concentration, which is greater in the case of HR-MAS by 15%. Several hypotheses could explain this. (i) A small fraction of the pollutant interacting with the surface was not present after centrifugation and thus neither observed by HPLC nor ^1H liquid state NMR. (ii) The interaction affecting BTSO_3 and DSS relaxation properties may interfere in quantification. However, T_1 of both BTSO_3 and DSS decreased by about 10%. Consequently, the relative concentration may not be different. (iii) The spinning rate increased molecular diffusion and the LDH adsorption capacities of one compound compared with batch equilibrium experiments made as described in the OECD Guideline 106 (OECD, 2000) (i.e. not in a HR-MAS NMR rotor). This hypothesis was not consistent with the T_1 data and quantification experiments carried out under the same conditions (solid-liquid ratio, spinning rate, temperature). Thus, one of the most probable reasons was the influence of cells. Indeed, the adsorption of BTSO_3 or DSS on cells was highly likely as such phenomena have often been described in liquid media. A similar hypothesis would be that cells generate macromolecules that affect adsorption properties of BTSO_3 or DSS. In contrast, the ^1H HR-MAS NMR showed that the organic compounds interact with the solid at the solid-liquid interface, although adsorption isotherms did not suggest it. This requires further investigation.

Figure 11 Time course of BTSO₃ concentration in the presence of 10 mg of Mg₃AlCO₃ LDH phase determined by ¹H liquid state NMR after centrifugation (○) and by ¹H HR-MAS NMR performed directly on the raw medium (□).

Conclusions

We found that although NMR application is limited to laboratory experiments, it is a unique tool to assess these mechanisms at a molecular level. It appears that (HR) MAS NMR spectroscopy allows direct –*in situ*– observation of the adsorption mechanism at the surface of a colloid. Although observed chemical shifts correspond to an average of several molecules on the NMR time-scale, it clearly appears in this work that the intensity of the detected signals can be analysed in terms of intensity of the interaction involved. The mobility of a pollutant at the surface of solid matrix can thus be assessed; in particular, HR-MAS is very promising in differentiating molecular species according to their degree of mobility in hydrated matrices. In the present communication, we have illustrated the potential of various MAS NMR approaches with the case studies of the interactions of three organic pollutants, glyphosate, MCPA and BTSO₃, with clay materials. It was shown that CPMAS ¹³C NMR did not give any conclusive information; in contrast ¹H (HR) MAS NMR gave complementary information including T₁ values, mobility and quantification of this pollutant loaded at the surface of a solid matrix. Although the NMR technique remains quite insensitive, ¹H can be detected relatively easily at natural abundance (*vide supra*). We have shown that these techniques could be applied both on synthetic anionic clays close to hydrotalcites but also on natural cationic clays such as montmorillonites. This methodology was also successfully applied to monitor the biodegradation of xenobiotics by microorganisms in model soil, directly *in situ*; in the future it may be interesting to correlate the level of a pollutant loaded at the surface of a soil component – and the interactions involved – to its bioavailability. Dynamic properties of the pollutants, obtained by various relaxation measurement experiments performed on hydrated samples, will be reasonably key points to reach this objective.
